## ABSTRACT

Modern information management applications often require integrating data from a variety of data sources, some of which may copy or buy data from other sources. When these data sources model a dynamically changing world (*e.g.*, people’s contact information changes over time, restaurants open and go out of business), sources often provide out-of-date data. Errors can also creep into data when sources are updated often. Given out-of-date and erroneous data provided by different, possibly dependent, sources, it is challenging for data integration systems to provide the true values. Straightforward ways to resolve such inconsistencies (*e.g.*, voting) may lead to noisy results, often with detrimental consequences.

In this paper, we study the problem of finding true values and determining the copying relationship between sources, when the update history of the sources is known. We model the quality of sources over time by their *coverage*, *exactness* and *freshness*. Based on these measures, we conduct a probabilistic analysis. First, we develop a Hidden Markov Model that decides whether a source is a copier of another source and identifies the specific moments at which it copies. Second, we develop a Bayesian model that aggregates information from the sources to decide the true value for a data item, and the evolution of the true values over time. Experimental results on both real-world and synthetic data show high accuracy and scalability of our techniques.

## 1. INTRODUCTION

Modern information management applications often require integrating data from a variety of data sources. Among these sources, some may copy others (often without proper attribution on the web), crawl or aggregate data from others (*e.g.*, Google), exchange data with or buy data from other sources [1]. Sources often provide out-of-date and erroneous data, and such data can be propagated by copiers. Resolving conflicts in data from different sources and determining the true values is critical for improving quality of integrated data. Recent work on this topic focuses on resolving conflicts from a snapshot of data [5, 12]. However, the real world is dynamically changing (*e.g.*, people’s contact information changes

over time, restaurants open and go out of business), and sources often frequently update their data to capture the changes. Such evolution presents new challenges to truth discovery.

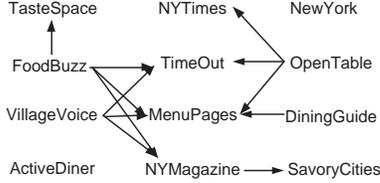

First, true values can evolve over time and in many applications we are interested in the whole history or a fragment of the history of true values for particular items (*e.g.*, a person’s addresses in the past five years, the history of a customer’s billing information, and the previous chairs of an organization). However, errors can creep into data and data can go out of date. It is challenging to determine which values were once true and in which periods they were true.

Second, sources are often of different quality and a natural thought is to take this into consideration when we decide true values. However, low-quality data can be caused by many reasons: some sources make a lot of errors in their provided data; some provide correct data but fail to update according to later changes; and some, though they update, do so slowly. All these reasons can lead to a low accuracy of a snapshot of data and we should treat them differently.

Third, a source may copy data from other sources and often copy erroneous and out-of-date data unknowingly. Straightforward ways to resolve conflicts (*e.g.*, voting) fall short in presence of copying. In addition, the copying relationship can evolve over time as well: a source can stop copying and become independent, can change sources from which it copies, and can copy at some times and provide data independently at other times. These can make copying detection extremely tricky.

**EXAMPLE 1.1.** *We collected data on Manhattan restaurants from 12 web sources (listed in Table 1) weekly from 1/2009 to 3/2009 and examined opening and closing of restaurants. There are 5269 restaurants mentioned by at least 2 data sources and among them we found that 280 went out of business recently.*

*We decided the life period of each of the 5269 restaurants from the data and the copying relationship between the sources (shown*

**Figure 1: Copying relationship we discovered between sources in the motivating example. An arrow from one source to another indicates the former is a copier of the latter.**

in Fig. 1). Accordingly, we computed for each source its *coverage* (how many existing restaurants are provided and how many closed restaurants are removed), *exactness* (how many updates are correct at the time of being made), *freshness* (how quickly sources capture changes and update), and the number of closed restaurants they still provide in their lists (shown in Table 1)<sup>1</sup>. We observe that sources do provide stale data, their quality measures vary highly, and some do copy from others. In particular, we found that source FoodBuzz, which may be an aggregator, seems to have copied from several other sources, including some out-of-date listings, and accordingly has a lower exactness.  $\square$

In this paper, we examine the update history of sources and study how to decide the evolving copying relationship between sources and the evolving true values. Our first contribution is to propose several quality measures of data sources, which play a key role in our probabilistic analysis. These measures include *coverage*—how many values in the history a source covers, *exactness*—how many updates conform to the reality, and *freshness*—how quickly a source captures a new value (Sec. 2). These measures are orthogonal and all contribute to the accuracy of the latest version of the data, as a low accuracy of current data can be due to either a low exactness of provided data (erroneous data), or a low coverage or freshness for capturing recent changes (outdated data).

Our second contribution is a set of Hidden Markov Models (HMM) that decide whether a source copies from another source and at which moment it copies (Sec. 3). Our models consider not only whether two sources share similar update history while one often updates later than the other, but also the coverage, freshness and exactness of the sources, to avoid identifying slow updaters as copiers. In addition, although the copying relationship between a pair of sources can evolve over time, frequent radical change is less likely; in other words, a copier is more likely to remain as a copier. Our HMM models capture this intuition and so are able to make more accurate decisions both on the copying relationship and on when the copying is conducted.

Third, we develop a Bayesian model to decide when the true value for a particular data item changes and what the new value is (Sec. 4). Our model considers both source quality and data copying, and so is less affected by possible wrong updates, stale data, and copied data. In addition, we consider different publish patterns, such as a source instantly publishing collected data, and publishing data collected over a period of time in a batch mode (Sec. 5).

We describe experimental results on both real-world data and synthetic data, showing that our models are accurate and scalable both in detection of the evolving copying relationship and discovery of evolution of true values (Sec. 6).

We note that although we propose our techniques in the framework of truth discovery, our techniques for detecting copying and

<sup>1</sup>We describe the data set, the measures, and our techniques in detail in the rest of this paper. As we show in Sec. 6, we have evidence to support some copyings we discovered.

evaluating source quality are of independent interest in a variety of data-integration tasks, including source recommendation, plagiarism detection, query optimization in data integration, and so on.

## 2. OVERVIEW

This section formally defines the problem we solve in this paper and defines quality measures of data sources.

### 2.1 Problem definition

Let  $\mathcal{O}$  be a set of objects, each representing a particular aspect of a real-world entity, such as the affiliation of a person. We assume the problem of schema matching and object resolution has already been solved using existing techniques, so each object has a unique identity. Each object  $O \in \mathcal{O}$  is associated with a value at a particular time  $t$  and can be associated with different values at different times; if  $O$  does not exist at  $t$ , we consider it associated with a special value  $\perp$ . Formally, we define the *life span* of  $O$  as a sequence of *transitions*  $(tr_1, v_1), \dots, (tr_l, v_l)$ , where (1)  $l$  is the number of periods in  $O$ 's life time; (2) the value of  $O$  changes to  $v_i$  at time  $tr_i, i \in [1, l]$ ; (3)  $v_i \neq \perp$ , and  $v_i \neq v_{i+1}$  for each  $i \in [1, l-1]$ ; and (4)  $tr_1 < tr_2 < \dots < tr_l$ . We denote by  $\odot$  the beginning time we are interested in and  $tr_1 = \odot$  if an object already exists at that time. In our paper we focus on atomic categorical values; we can treat set (or list) of atomic values as a whole and adapt techniques in [5] for value similarity. As a special case,  $O$  can be associated with only two values, exist and non-exist ( $\perp$ ), so its life span describes appearing and disappearing of  $O$  (Example 1.1).

Let  $\mathcal{S}$  be a set of structured data sources. Each source  $S \in \mathcal{S}$  can (but not necessarily) provide a value for an object at a particular time, and can change the value over time. We observe data provided by the sources at different times; by comparing an observation with its previous observation, we can infer recent *updates*. Formally, we denote by  $\mathbf{T} = \{t_0, \dots, t_n\}$  the set of observation points and by  $\bar{U}(S, t_i), i \in [0, n]$ , the updates we infer at time  $t_i$ ; as a special case,  $\bar{U}(S, t_0)$  contains values  $S$  provided at  $t_0$ <sup>2</sup>. Note that an update in  $\bar{U}(S, t_i), i \in [1, n]$ , can happen at any time in  $(t_{i-1}, t_i]$  and we may miss updates that are overwritten before the next observation; thus, frequent collection can often preserve more information and benefit our techniques. Our techniques can be adapted to the case where we know exact timestamps of each update.

We classify data sources into *independent* ones and *copiers*. An independent source updates according to its own observation of the real world. A copier can copy from one or more other sources. When a copier copies, it may copy only a subset of updates and may meanwhile observe the real world independently and conduct updates accordingly (validating or modifying a copied value is also considered as independent updating). A copier may not copy all the time: it can copy at some times and update independently at other times. In addition, a copier can stop copying from a particular source and vice versa. Note that the case of a source being independent and the case of a source being a copier but not copying at a particular moment are conceptually different, but not distinguishable from behavior of the source at that moment.

For now we consider *instant publishing*—publishing a value right after it is observed (from the real world or from another source); in other words, the published updates conform to the observation at the point of publishing (though the observation may not conform to the reality). We consider other publish patterns in Sec. 5.

<sup>2</sup>We assume a source starts providing data before  $t_0$ , but our techniques can be easily adapted for the opposite case.

**Table 2: Researcher affiliation example. The last update on each object by each source is in bold font.**

$H$ ( $\odot$ , UW) (05, Google)	(00, UW) (07, <b>Google</b> )	(00, Wisc) (02, UW) (05, <b>Google</b> )	(01, Wisc) (06, <b>UW</b> )	(05, <b>UW</b> )	(03, Wisc) (05, Google) (07, <b>UW</b> )

EXAMPLE 2.1. Consider the (synthetic) data sources in Table 2. They provide information on affiliations of five database researchers—Stonebraker(S), Dewitt(D), Bernstein(B), Carey(C), Halevy(H), and we observe their data each year since 2000. Among the five sources,  $S_1$  and  $S_2$  are independent;  $S_3$  was once a copier of  $S_2$  and then changed to be a copier of  $S_1$  since 2006 (despite difference of their latest data);  $S_4$  is a copier of  $S_1$ ;  $S_5$  is a copier of  $S_3$  but copies only periodically (in 2003 and 2007).  $\square$

Our goal is to determine the evolving copying relationship between sources and the evolving true values of objects. Formally, we decide

1. *copying*: for every  $S_1, S_2 \in \mathcal{S}$  and  $t \in \mathbf{T}$ , the probability that  $S_1$  is a copier of  $S_2$  at  $t$  and if so, the probability of  $S_1$  actively copying from  $S_2$  at  $t$ ;
2. *life span*: for every object  $O \in \mathcal{O}$  and  $t \in \mathbf{T}$ , the true value (including  $\perp$ ) of  $O$  at  $t$ .

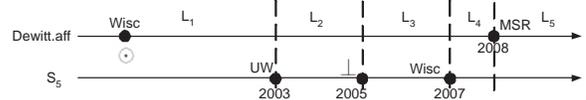

In this paper we do not consider simultaneous cyclic copying, which happens rarely in practice.

## 2.2 Quality of data sources

We first introduce three quality measures of data sources, namely, *coverage*, *exactness*, and *freshness*, as a whole referred to as the *CEF-measure*, on which we rely heavily in our probabilistic analysis. Ideally, a high-quality source should provide a new value for an object *if and only if*, and *right after*, the true value of the object evolves to that value; we capture these three conditions by the three measures respectively. Specifically, given a source, its coverage measures the percentage of all transitions of different objects that it captures; its (in)exactness measures the percentage of all transitions it mis-captures (by providing a wrong value); its freshness measures how quickly it captures the transitions. The definition of CEF-measure relies on two notions, *capture* and *mis-capture*, which we define next.

Consider a source  $S \in \mathcal{S}$ . An update of  $S$  on a particular object  $O$  can be triggered either by a transition of  $O$  (to reflect the value change) or by a previous update of  $S$  (to fix a previous error). Thus, we consider all transition points of  $O$  and update points of  $S$  on  $O$  and sort them in ascending order. These points divide the whole observation period into a set of *slices*. The real value of  $O$  in each slice is the real value at the beginning of the slice. As an example, Fig. 2 depicts the life span of Dewitt’s affiliation and updates by  $S_5$  on it; we divide the whole observation period into 5 slices.

A slice is *capturable* if at its beginning, the value provided by  $S$  is different from the real value. A capturable slice is *captured* if it ends with an update of  $S$  to the real value. A slice is *mis-capturable* if  $S$  can update to a wrong value; when there are more

**Figure 2: Computing CEF measure for  $S_5$ .**

than two values in the domain of  $O$ , each slice is mis-capturable. A mis-capturable slice is *mis-captured* if it ends with an update of  $S$  to a wrong value<sup>3</sup>. Thus, a slice that does not end with an update is neither captured nor mis-captured. In Fig. 2, all 5 slices are mis-capturable, and  $L_1, L_2, L_3$ , and  $L_5$  are capturable; among them,  $L_1$  and  $L_2$  are mis-captured, and  $L_3$  is captured.

We denote by  $cl(S, O)$ ,  $c(S, O)$ ,  $ml(S, O)$ , and  $m(S, O)$ , respectively, the number of capturable, captured, mis-capturable, and mis-captured slices for  $S$  on  $O$ . We define the coverage of  $S$ , denoted by  $C(S)$ , as

$$C(S) = \frac{\sum_{O \in \mathcal{O}} c(S, O)}{\sum_{O \in \mathcal{O}} cl(S, O)}. \quad (1)$$

We define the exactness of  $S$ , denoted by  $E(S)$ , as

$$E(S) = 1 - \frac{\sum_{O \in \mathcal{O}} m(S, O)}{\sum_{O \in \mathcal{O}} ml(S, O)}. \quad (2)$$

We define freshness of  $S$  by a distribution function of length of the captured slices. We denote by  $c(S) = \sum_{O \in \mathcal{O}} c(S, O)$ , and by  $c_\Delta(S)$ ,  $\Delta \geq 0$ , the number of captured slices with length no larger than  $\Delta$ . Then, the freshness function of  $S$ , denoted by  $F(S, \Delta)$ , can be computed as follows (thus,  $F(S, +\infty) = 1$ ).

$$F(S, \Delta) = \frac{c_\Delta(S)}{c(S)}. \quad (3)$$

Note that the three different measures are orthogonal and all contribute to the accuracy of data provided by the source at any moment: low exactness causes erroneous data whereas low coverage or freshness causes out-of-date data.

In practice, it is often easier to capture a long slice than a short one, and easier to make a mistake during a long slice than a short one. We can thus compute the weighted measure, where the weight of a capturable slice is proportional to its length and that of a mis-capturable slice is inversely proportional to its length. Our experimental results show higher accuracy with weighted CEF-measure.

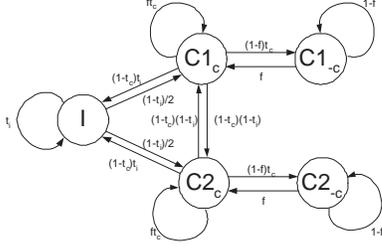

## 3. DISCOVERING COPYING OF SOURCES

This section describes how we discover copying between data sources. As we need to reason about update pattern over time, a natural choice is to use a Hidden Markov Model (we compare with other options and validate its advantage in experiments (Fig. 16)). We start from a review of the HMM model (Sec. 3.1), then describe a basic HMM model for copying discovery (Sec. 3.2), and next extend it for periodical copying (Sec. 3.3). This section assumes knowledge of the life span of each object and we present how we compute it in Sec. 4.

### 3.1 Review of HMM

A Hidden Markov Model (HMM) [10] contains a set of *hidden states*  $\mathbf{H} = \{h_1, h_2, \dots, h_N\}$ ,  $N > 1$ , and a set of observation symbols  $\mathbf{O} = \{o_1, o_2, \dots, o_M\}$ ,  $M > 1$ . At each time  $t$ , the model is in a particular hidden state  $q_t \in \mathbf{H}$  and we observe a particular observation symbol  $e_t \in \mathbf{O}$ . An HMM  $\lambda = (A, B, \pi)$  contains three components:

<sup>3</sup>In the rest of the paper, when a transition and an update on the same object occur between two consecutive observations, in absence of knowledge of which happens earlier, we treat the update as correct once its value conforms to the value of the new transition or that of the previous transition.

**Figure 3: Hidden states and transitions in the basic HMM model.**

- the state transition probabilities,  $A_{N,N} = \{a_{ij} | i, j \in [1, N]\}$ , where  $a_{ij} = P(q_{t+1} = h_j | q_t = h_i)$  is the probability that the model transitions from state  $h_i$  to  $h_j$ ;
- the observation probability distribution in each state,  $B_{N,M} = \{b_{ij} | i \in [1, N], j \in [1, M]\}$ , where  $b_{ij} = P(o_j | q_t = h_i)$  is the probability of observing  $o_j$  in state  $h_i$ ;
- the initial state distribution,  $\pi_N = \{\pi_i | i \in [1, N]\}$ , where  $\pi_i = P(q_1 = h_i)$  is the initial probability of state  $S_i$ .

Given a sequence of observations, we can apply *Forward-backward* inference to decide the probability of each state at each time point. In addition, by applying *Baum-Welch* learning, we can decide the parameters in  $A$ ,  $B$  and  $\pi$  from a set of observation sequences [10].

## 3.2 The basic HMM

Let  $S_1$  and  $S_2$  be two data sources. We decide if one of them copies from the other. We apply an HMM, where the hidden states correspond to whether  $S_1$  or  $S_2$  is copying at a particular moment and the observations correspond to their updates. We next describe our model in detail.

### 3.2.1 Hidden states

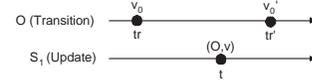

We first decide the set of hidden states. As we assume acyclic copying, at each moment there can be at most one copier between  $S_1$  and  $S_2$ . In case a particular source is a copier, it can copy or independently update at a particular observation point. Thus, there are five hidden states:  $I$ ,  $C1_c$ ,  $C1_{-c}$ ,  $C2_c$ , and  $C2_{-c}$ . State  $I$  represents independence of  $S_1$  and  $S_2$ . States  $C1_c$  and  $C1_{-c}$  represent that  $S_1$  is a copier of  $S_2$ ; the former represents  $S_1$  actively copying from  $S_2$  and the latter represents  $S_1$  not copying at that moment. Similarly, states  $C2_c$  and  $C2_{-c}$  represent  $S_2$  copying or not copying while being a copier of  $S_1$ .

Note that  $C1_{-c}$ ,  $C2_{-c}$ , and  $I$  are not distinguishable from the action of  $S_1$  and  $S_2$ : in all cases  $S_1$  and  $S_2$  make independent updates. We separate them because the probability of transition from one of these states to state  $C1_c$  (or  $C2_c$ ) can be different: intuitively,  $S_1$  is more likely to actively copy from  $S_2$  (so in state  $C1_c$ ) next when it is in state  $C1_{-c}$  than in state  $I$ . To avoid ambiguity, we disallow transition between  $C1_{-c}$  and any of  $I$ ,  $C2_c$ , and  $C2_{-c}$  (similar for  $C2_{-c}$ ); thus, the period of  $S_1$  being a copier starts from and ends after a real copying. Fig. 3 shows the transition graph.

### 3.2.2 Initial and transition probabilities

We now consider how to assign initial and transition probabilities for the states. Note that many transitions include the same behavior, such as transformation between being a copier and being independent; thus, instead of having different transition probabilities for the 15 possible transitions, we can compute them using only a few parameters, as we describe next.

Since the period of a source being a copier starts with a real copying, the initial state cannot be  $C1_{-c}$  or  $C2_{-c}$ . Assume the a-priori probability of two sources being independent is  $\alpha$  (parameters can

**Figure 4: An update and its previous transition.**

be learned from real data by *Baum-Welch* learning). Then, we have initial probabilities as

$$P(I) = \alpha, \quad (4)$$

$$P(C1_c) = P(C2_c) = \frac{1 - \alpha}{2}. \quad (5)$$

We next define three parameters that we use to compute probabilities of transitions between states.

- $f$  ( $0 < f \leq 1$ ): the probability that a copier copies at a particular time point.
- $t_c$  ( $0 \leq t_c \leq 1$ ): the probability that between a pair of sources, a copier remains as a copier of the other source. Intuitively, this is more likely to happen than transformation to independence, so typically  $t_c > .5$ .
- $t_i$  ( $0 \leq t_i \leq 1$ ): the probability that a pair of independent sources remain as independent. Typically,  $t_i > .5$ .

The probabilities of transitions are computed as follows. For convenience, we denote by  $T_{h,h'}$  the transition from state  $h$  to  $h'$  and by  $a_{h,h'}$  its probability.

- Transition  $T_{I,I}$  happens when  $S_1$  and  $S_2$  remain as independent, so has probability  $t_i$ . Transitions  $T_{I,C1_c}$  and  $T_{I,C2_c}$  have the same probability,  $\frac{1-t_i}{2}$ .
- When  $S_1$  is a copier of  $S_2$ , it transforms to be independent with probability  $1 - t_c$ . Then,  $S_1$  and  $S_2$  become independent; they remain so with probability  $t_i$ , and otherwise,  $S_2$  becomes a copier of  $S_1$ . Thus,  $a_{C1_c,I} = (1 - t_c) \cdot t_i$  and  $a_{C1_c,C2_c} = (1 - t_c)(1 - t_i)$  (similar for  $C2_c$ ).
- Once  $S_1$  remains as a copier of  $S_2$ , it copies at a particular moment with probability  $f$ . At state  $C1_c$ ,  $S_1$  remains as a copier with probability  $t_c$ , so  $a_{C1_c,C1_c} = f \cdot t_c$  and  $a_{C1_c,C1_{-c}} = (1 - f) \cdot t_c$ . At state  $C1_{-c}$ ,  $S_1$  has to remain as a copier, so  $a_{C1_{-c},C1_c} = f$  and  $a_{C1_{-c},C1_{-c}} = 1 - f$  (similar for  $C2_c$  and  $C2_{-c}$ ).

### 3.2.3 Observation probability distribution

Now we consider the probability of  $S_1$  and  $S_2$  making particular sets of updates in a state. There are a huge number of possible updates for each source at each moment; enumerating them and assigning a probability for each is infeasible. Instead, we describe equations for computing the probability of a particular observation.

We focus our attention on three types of updates at each particular point: those made by  $S_1$  and recently (we define ‘recently’ shortly) by  $S_2$ , denoted by  $\bar{U}_{S_1,S_2}$ ; those made by  $S_2$  before, but not by  $S_1$ , denoted by  $\bar{U}_{-S_1,S_2}$ ; and those made by  $S_1$  but not recently by  $S_2$ , denoted by  $\bar{U}_{S_1,-S_2}$ . Typically, the more updates in  $\bar{U}_{S_1,S_2}$ , the more likely that  $S_1$  is copying from  $S_2$ ; the more updates in  $\bar{U}_{-S_1,S_2}$  and  $\bar{U}_{S_1,-S_2}$ , the less likely that  $S_1$  is copying. Note that we do not consider updates performed neither by  $S_1$  and  $S_2$ , both because enumerating them is often infeasible, and because the set of updates that ‘should’ be performed depends on previous updates and so varies for sources. We denote by  $\Omega_1$  the distribution of  $\bar{U}_{S_1,S_2}$ ,  $\bar{U}_{S_1,-S_2}$ ,  $\bar{U}_{-S_1,S_2}$  at a particular moment and define  $\Omega_2$  for  $S_2$  similarly (note that  $\bar{U}_{S_1,S_2}$  and  $\bar{U}_{S_2,S_1}$  can be different, similar for other pairs of sets). We summarize observations at each point using  $\Omega_1$  and  $\Omega_2$ .

Intuitively, the fact that  $S_1$  always follows updates of  $S_2$  can ring an alarm in copying detection. However, this fact in itself does

not necessarily imply  $S_1$  being a copier, as  $S_1$  might just be a slow updater (has low freshness). Source  $S_1$  is more likely to be a copier of  $S_2$  if in addition one of the following holds: (1)  $S_1$  and  $S_2$  have only low to medium coverage but their updates highly overlap in a close time frame; (2)  $S_1$  and  $S_2$  make a lot of common mistakes (e.g., source  $S_2$  and  $S_3$  in Example 2.1); (3) the overlapped updates are performed by  $S_1$  after the real values have already changed (e.g., source  $S_3$  and  $S_5$ 's updates on *Halevy*'s affiliation after 2005 in Example 2.1). These three cases are more suspectable because they are low-probability events if  $S_1$  and  $S_2$  are independent. We next examine the probability of an update by a source conditioned on the source independently updating or copying.

We first consider the case where  $S_1$  is independently updating, denoted by  $S_1 \not\rightarrow S_2$ , and compute the probability that  $S_1$  makes an update  $U$  at time  $t$ . Assume  $U$  updates the value of  $O$  to  $v$  and the last transition on  $O$  by time  $t$  is  $(tr, v_0)$  (Fig. 4). If  $v = v_0$ , the update is correct— $S_1$  does not make a mistake and captures the correct value within time  $t - tr$ , so the probability is

$$P(U, S_1, t | S_1 \not\rightarrow S_2, U \text{ true}) = E(S_1)C(S_1)F(S_1, t - tr). \quad (6)$$

If instead,  $v \neq v_0$ ,  $S$  makes a mistake. Let  $m$  be the number of wrong values in the domain. Not assuming a-priori knowledge on which wrong values are more likely to be provided, we have<sup>4</sup>

$$P(U, S_1, t | S_1 \not\rightarrow S_2, U \text{ false}) = \frac{1 - E(S)}{m}. \quad (7)$$

We denote the probability of  $S_1$  performing  $U$  by  $P(U)$ . According to if  $U$  is correct or not, we apply Equation (6) or (7) to compute  $P(U)$ . Obviously,

$$P(U \in \bar{U}_{S_1, S_2} \cup \bar{U}_{S_1, \neg S_2} | S_1 \not\rightarrow S_2) = P(U); \quad (8)$$

$$P(U \in \bar{U}_{\neg S_1, S_2} | S_1 \not\rightarrow S_2) = 1 - P(U). \quad (9)$$

We next consider the case where  $S_1$  is copying from  $S_2$ , denoted by  $S_1 \rightarrow S_2$ . Then,  $S_1$  copies a subset of recent updates by  $S_2$  and can also update independently. Let  $s$  be the *selectivity* of a copier (i.e., probability of copying an update). If we denote by  $P_c(U)$  the probability that a copier independently performs an update  $U$ , for  $S_2$ 's recent updates, we have

$$P(U \in \bar{U}_{S_1, S_2} | S_1 \rightarrow S_2) = s + (1 - s)P_c(U); \quad (10)$$

$$P(U \in \bar{U}_{\neg S_1, S_2} | S_1 \rightarrow S_2) = (1 - s)(1 - P_c(U)). \quad (11)$$

For an update not performed by  $S_2$  recently, we have

$$P(U \in \bar{U}_{S_1, \neg S_2} | S_1 \rightarrow S_2) = P_c(U). \quad (12)$$

We compute  $P_c(U)$  in the same way as  $P(U)$ ; however, we should use different CEF-measure for  $S_1$  here: that of updates by  $S_1$  but not previously by  $S_2$ . Computing such measure introduces a big overhead, as we need to compute for every pair of sources. We can approximate by assuming  $S_1$  and  $S_2$  have the same number of capturable and mis-capturable slices and so computing by

$$C(S_1 | S_2) = C(S_1) - sC(S_2); \quad (13)$$

$$E(S_1 | S_2) = E(S_1) + s(1 - E(S_2)); \quad (14)$$

$$F(S_1, \Delta | S_2) = F(S_1, \Delta). \quad (15)$$

Our experiments show that such approximation significantly reduces execution time without affecting the results much.

To make our computation tractable, we assume independence of updates by one source and can thus compute  $P(\Omega_1 | S_1 \rightarrow S_2)$  and  $P(\Omega_1 | S_1 \not\rightarrow S_2)$  (our model with this assumption already obtains high accuracy on real-world data and synthetic data in our experiments; we leave consideration of update correlation for future work). Then, the probability of observations  $(\Omega_1, \Omega_2)$  for each state comes along naturally:

<sup>4</sup>We can incorporate techniques in [5] for non-uniform value distribution.

**Table 3: Observation  $\Omega$  for  $S_5$  with respect to  $S_3$  in Example 2.1. We skip the years when all sets are empty.**

Year	$\bar{U}_{S_5, S_3}$	$\bar{U}_{\neg S_5, S_3}$	$\bar{U}_{S_5, \neg S_3}$
2003	{(S, UCB), (B, MSR), (H, Wisc)}	$\emptyset$	{(D, UW)}
2005	$\emptyset$	$\emptyset$	{(S, MS), (D, $\perp$ ), (H, Google)}
2007	{(D, Wisc), (C, BEA), (H, UW)}	$\emptyset$	$\emptyset$
2009	$\emptyset$	{(S, MIT)}	$\emptyset$

**Table 4: Probabilities of hidden states for  $S_5$  vs.  $S_3$ .**

State	03	04	05	06	07	08	09
Copy ( $C1_c$ )	1	.43	.02	.43	1	.39	.12
Idle ( $C1_{\neg c}$ )	0	.51	.89	.51	0	.35	.52

$$P(\Omega_1, \Omega_2 | I) = P(\Omega_1, \Omega_2 | C1_{\neg c}) = P(\Omega_1, \Omega_2 | C2_{\neg c}) \\ = P(\Omega_1 | S_1 \not\rightarrow S_2) \cdot P(\Omega_2 | S_2 \not\rightarrow S_1); \quad (16)$$

$$P(\Omega_1, \Omega_2 | C1_c) = P(\Omega_1 | S_1 \rightarrow S_2) \cdot P(\Omega_2 | S_2 \not\rightarrow S_1); \quad (17)$$

$$P(\Omega_1, \Omega_2 | C2_c) = P(\Omega_1 | S_1 \not\rightarrow S_2) \cdot P(\Omega_2 | S_2 \rightarrow S_1). \quad (18)$$

Note that since states  $C1_{\neg c}$ ,  $C2_{\neg c}$  and  $I$  are not distinguishable from the behavior of the data sources, the probabilities of  $\Omega_1$  and  $\Omega_2$  conditioned on them are the same.

We now present several features of our model that conform to the intuition presented early in our discussion (the proof is given in the full version of the paper [4].)

**THEOREM 3.1.** *Let  $s$  be the selectivity of copying and  $m$  be the number of wrong values in the domain. The observation probability distribution has the following properties:*

1. if  $C(S_1) < s$ , adding a correct update to  $\bar{U}_{S_1, S_2}$  at time  $t$  increases probability of state  $C1_c$  at  $t$ , and adding a correct update to  $\bar{U}_{\neg S_1, S_2}$  decreases that probability;
2. if  $m > \frac{1}{s}$ , adding a wrong update to  $\bar{U}_{S_1, S_2}$  at time  $t$  increases probability of state  $C1_c$  at  $t$ , and adding a wrong update to  $\bar{U}_{\neg S_1, S_2}$  decreases that probability;
3. if  $E(S_1) > .5$ , adding a correct update to  $\bar{U}_{S_1, \neg S_2}$  at time  $t$  decreases probability of state  $C1_c$  at  $t$ ;
4. adding a wrong update to  $\bar{U}_{S_1, \neg S_2}$  at time  $t$  decreases probability of state  $C1_c$  at  $t$ .  $\square$

**Recent updates:** We next define what we mean by a *recent* update by a source. To avoid penalizing updates that are not copied immediately, we consider a *window* of size  $W$ . Assume  $S_1$  makes  $W + 1$  consecutive copyings at time  $t_{k_0}, \dots, t_{k_w}$ ,  $0 \leq k_0 < \dots < k_w \leq n$  (recall that  $t_n$  is the last observation). The *recent* updates by  $S_2$  include all of its updates at time  $(t_{k_0}, t_{k_w}]$ , not overwritten by  $S_2$ 's later updates on the same objects, and not performed by  $S_1$  yet. Here, we mark a time point as a possible ‘‘copying’’ point if updates by  $S_1$  at that time overlap with recent updates by  $S_2$ .

**EXAMPLE 3.2.** *Consider sources  $S_3$  and  $S_5$  in the motivating example. Table 3 shows  $\Omega$  for  $S_5$  with respect to  $S_3$ . Year 2003 and 2007 are considered as copying points. As an example,  $S_5$  has four updates in 2003: three overlap with  $S_3$ 's recent updates and are in  $U_{S_5, S_3}$ , and one, (Dewitt, UW), does not overlap and is in  $U_{S_5, \neg S_3}$  ( $S_3$ 's update (Dewitt, UW) in 2001 is later overwritten in 2002).*

*Table 4 shows the probability of states  $C1_c$  and  $C1_{\neg c}$  we infer for  $S_5$  vs.  $S_3$  (we set  $t_c = t_i = .9$ ,  $f = .5$ ). Thus, our HMM model is able to identify that  $S_5$  is a copier of  $S_3$ , copying in the years of 2003 and 2007.  $\square$*

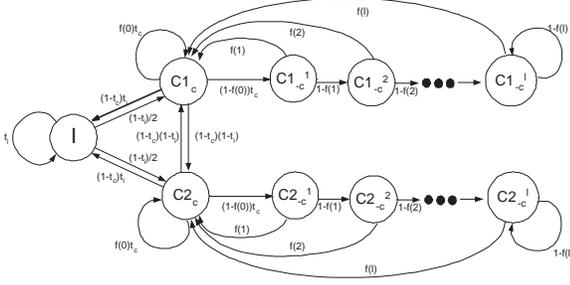

Figure 5: Hidden states and transitions in the timespan HMM model.

### 3.3 Considering time span

Once a source remains as a copier, it copies sooner or later. Typically, the longer it has not copied yet, the more likely that it copies next. It is also possible that a copier copies periodically: it makes independent updates for a period of time and then copies the recent updates by the original source.

To capture these intuitions, we need to reason about the time period that a copier has been independently updating; however, first-order Markov, where the probability of falling in a hidden state only relies on the state at the previous time, cannot capture this naturally. As we only care about the time period of state  $C1_{-c}$  and  $C2_{-c}$ , we stick to first-order Markov, which is easy for learning and inference, and revise our HMM model by dividing state  $C1_{-c}$  (similar for  $C2_{-c}$ ) into a set of states  $C1_{-c}^1, C1_{-c}^2, \dots, C1_{-c}^q$ , where  $q$  is the number of observations within which a copier typically will conduct at least one copying (we discuss how to set  $q$  soon). Among  $C1_{-c}^1, C1_{-c}^2, \dots, C1_{-c}^q, C1_c$  can transit only to state  $C1_{-c}^1$ ; for each  $i \in [1, q]$ ,  $C1_{-c}^i$  can transit either to  $C1_{-c}^{i+1}$  or to  $C1_c$ ; finally,  $C1_c$  can transit to itself or to  $C1_c$ . Essentially, for a state  $C1_{-c}^i$ ,  $i$  acts as a timer to count for how long  $S_1$  has not copied yet. Note that this model is more meaningful when the lengths of time between consecutive observations are similar.

Fig. 5 shows the revised HMM model, where  $f(i), i \in [1, q]$ , is the transition probability from  $C1_{-c}^i$  to  $C1_c$  and  $f(0)$  is this probability from  $C1_c$  when  $S_1$  remains as a copier (with probability  $t_c$ ). There are various ways to define  $f(i)$  and we give a few examples.

- If we set them all as the same, the model is reduced to the basic HMM model (Fig. 3).
- According to the intuition that the longer a copier has not copied, the more likely that it will copy next, we can use an attenuation function such as

$$f(i) = \frac{i+f}{i+1}, f \in (0, 1). \quad (19)$$

So  $f(0) = f$  and  $f(q) \rightarrow 1$ . We can set  $q$  as the minimum  $i$  such that  $f(i) > 1 - \theta$ , where  $\theta$  is a number close to 0.

- To model periodical copying where the copier copies once every  $k$  observations, we can set  $q = k$ ,  $f(i) = \theta$  for every  $i \in [0, k)$  and  $f(i) = 1 - \theta$  for  $i = k$ .

Finally, we can learn  $f(i)$  by *Baum-Welch* learning. As different sources can have different copying patterns, this learning is *local* and is performed for *each* pair of sources, different from the *global* learning of other parameters.

## 4. DISCOVERING LIFE SPAN OF OBJECTS

We now present a Bayesian model that decides life span of an object. We start by considering a set of independent sources (Sec. 4.1), then extend our model by considering copiers (Sec. 4.2), and finally present the complete algorithm (Sec. 4.3).

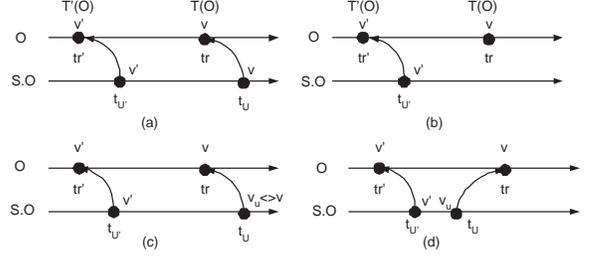

Figure 6: Possibilities of the next update,  $U(S)$ .

### 4.1 Deciding life span

Consider an object  $O \in \mathcal{O}$ . To discover its life span, we need to decide both time and value of each transition. We proceed iteratively: we first decide the value of  $O$  at time  $t_0$ , then find the most likely time point and value for  $O$ 's next transition, and repeat this process until we decide there is no more transition. Note that the transition points we decide have to be some observation points; in presence of precise time stamp of updates, we can extend our algorithm for more fine-grained results.

**Deciding the initial value** We denote by  $\Psi$  our observation of which value each source  $S \in \mathcal{S}$  initially provides for  $O$ . Let  $\mathcal{V}(O)$  be the domain of  $O$ . Then, our goal is to find  $v \in \mathcal{V}(O)$  that maximizes  $P(v|\Psi)$ . According to the Bayes rule, we just need to find the  $v$  that maximizes  $P(\Psi|v)$ .

First, suppose  $v \neq \perp$ . Consider a source  $S \in \mathcal{S}$ . There are three cases for the initial value it provides for  $O$ :

- $S$  provides the correct value, with probability  $E(S)C(S)$  (we ignore freshness as the first observation contains updates accumulated over time);
- $S$  does not provide a value for  $O$ , with probability  $E(S)(1 - C(S))$ ;
- $S$  provides a wrong value, with probability  $\frac{1-E(S)}{m}$ .

We denote by  $\bar{S}(v)$  the set of sources providing  $v$  on  $O$  initially and by  $\bar{S}(\emptyset)$  the set of sources not providing any value on  $O$  initially. Assuming independence of sources, we have

$$P(\Psi|v) = \prod_{S \in \bar{S}(v)} E(S)C(S) \cdot \prod_{S \in \bar{S}(\emptyset)} E(S)(1 - C(S)) \cdot \prod_{S \in \mathcal{S} - \bar{S}(v) - \bar{S}(\emptyset)} \frac{1 - E(S)}{m}. \quad (20)$$

With similar analysis, when  $v = \perp$ , we have

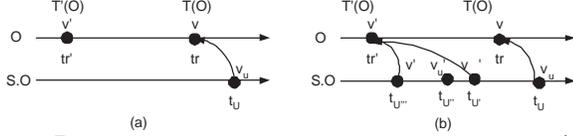

$$P(\Psi|\perp) = \prod_{S \in \bar{S}(\emptyset)} E(S) \cdot \prod_{S \in \mathcal{S} - \bar{S}(\emptyset)} \frac{1 - E(S)}{m}. \quad (21)$$

We can thus decide the initial value of  $O$  accordingly.

**Deciding the next transition** Deciding the next transition is harder than deciding the initial value, as we need to consider an additional dimension—the time. Essentially, we solve the following problem. Given the last transition  $T'(O) = (tr', v')$  we have discovered on  $O$ , decide the next transition  $T(O) = (tr, v), v \in \mathcal{V}(O), v \neq v', tr \geq tr'$  ( $T'(O)$  and  $T(O)$  can happen within the same observation period). We start from a simple case, where for each source  $S \in \mathcal{S}$ , there is an update at time  $t_{u'} \in [tr', tr)$  corresponding to  $T'(O)$  (we consider other possibilities shortly). We denote  $S$ 's next update by  $U(S)$  and the observation of  $U(S)$  for each  $S \in \mathcal{S}$  by  $\Phi$ . According to the Bayes rule, we need to find  $v$  and  $tr$  that maximizes  $P(\Phi|T(O) = (tr, v))$ .

If  $T(O) = (tr, v)$ , there are three possibilities for  $U(S)$ :

*Case 1.*  $S$  captures the transition by updating the value of  $O$  to  $v_c$  at time  $[tr, t_n]$  (recall that  $t_n$  is the last observation point in  $\mathbf{T}$ ) (Fig. 6(a)). The probability of not making an error and capturing the transition is  $E(S)C(S)$ , and the probability of capturing it at

**Figure 7: Possibilities of update(s) for the previous transition  $T'(O)$ .**

a particular point is decided by the freshness function. Thus (we assume  $F(S, \Delta) = 0$  when  $\Delta < 0$ ),

$$\begin{aligned} & P(U(S) = (t_u, v), t_u \in [tr, t_n] | T(O) = (tr, v)) \\ &= E(S)C(S) \int_{t_{u-1}-tr}^{t_u-tr} F(S, t) dt. \end{aligned} \quad (22)$$

*Case II.*  $S$  misses the transition by not updating at  $[tr, t_n]$  (Fig. 6(b)). The probability of not making an error but not capturing the transition either is then

$$P(\overline{U(S)} | T(O) = (tr, v)) = E(S) (1 - C(S)F(S, t_n - tr)). \quad (23)$$

*Case III.*  $S$  makes an error either by updating to a different value (Fig. 6(c)), or by updating before  $tr$  (Fig. 6(d)). The probability of making an error is  $1 - E(S)$ . The error can be made at any time between  $(t_{u'}, t_n]$ , so the probability of observing an error at each point  $t_u$  is  $\frac{t_u - t_{u-1}}{t_n - t_{u'}}$ . Among all values in  $\mathcal{V}(O)$ , the probability of providing a particular wrong value is approximately  $\frac{1}{m}$ . So

$$\begin{aligned} & P(U(S) = (t_u, v_u), t_u \in (t_{u'}, tr) \vee v_u \neq v | T(O) = (tr, v)) \\ &= \frac{(1 - E(S))(t_u - t_{u-1})}{m(t_n - t_{u'})}. \end{aligned} \quad (24)$$

As we assume independence of sources, we have

$$P(\Phi | T(O) = (tr, v)) = \prod_{S \in \mathcal{S}} P(U(S) | T(O) = (tr, v)). \quad (25)$$

We apply similar analysis in case there does not exist any more transition after  $T'$ , denoted by  $\overline{T(O)}$ . We have

$$P(\overline{U(S)} | \overline{T(O)}) = E(S); \quad (26)$$

$$P(U(S) = (t_u, v_u), t_u > t_{u'} | \overline{T(O)}) = \frac{(1 - E(S))(t_u - t_{u-1})}{m(t_n - t_{u'})}. \quad (27)$$

We can thus choose the pair of  $tr$  and  $v$  with the maximum value of  $P(\Phi | T(O) = (tr, v))$  as the next transition, or terminates when  $P(\Phi | \overline{T(O)})$  has the maximum value.

This Bayesian model has the following properties, conforming to the intuition that the more sources update the value of  $O$  to  $v$  in a close time frame, the more likely that the transition involves value  $v$  and happens before their updates.

**PROPOSITION 4.1.** *Let  $S$  be a source and  $T(O)$  be a transition. Among  $F(S, 0)$  and  $F(S, t_i) - F(S, t_{i-1})$ ,  $i \in [1, n]$ , let  $F_{max}(S)$  be the maximum one and  $F_{min}(S)$  be the minimum one. Consider  $\Psi_1, \Psi_2, \Psi_3$ , which differ only in that  $U(S)$  conforms to  $T(O)$ , does not exist, or does not conform to  $T(O)$ , respectively. Then,*

- If  $C(S) > \frac{1}{F(S,0) + F_{max}(S)}$ ,  $P(T(O) | \Psi_1) > P(T(O) | \Psi_2)$ ;
- If  $E(S) > \frac{1}{1 + mC(S)F_{min}(S)}$ ,  $P(T(O) | \Psi_1) > P(T(O) | \Psi_3)$ ;
- If  $E(S) > \frac{1}{1 + m(1 - C(S))}$ ,  $P(T(O) | \Psi_2) > P(T(O) | \Psi_3)$ .  $\square$

Finally, note that  $U(S)$  is defined as the update after the update corresponding to  $T'(O)$ , denoted by  $U'(S)$ . Intuitively,  $U'(S)$  should be an update that changes the value of  $O$  to  $v'$  in  $[tr', tr)$ . However, there can be three cases: (1) there is one and only one such update (Fig. 6), so we consider it as  $U'(S)$ ; (2) there is no such update (Fig. 7(a)), so we consider  $U'(S)$  not existing,  $U(S)$  as the first update after  $tr'$ , and  $t_u = tr'$ ; (3) there are multiple

```

---

**Figure 8: Algorithm LIFESPAN: decide copying between data sources and life span of objects.**

such updates (Fig. 7(b)). The third case is especially tricky because some of the updates may fix previous errors (so correspond to  $T'(O)$ ) and some may respond to later transitions. We conduct a simple voting on the value of each moment since  $tr'$ , and find the first point when the value of  $O$  changes from  $v'$  to another value. Accordingly, we consider updates to  $v'$  before this point as corresponding to  $T'(O)$  and choose the last one as  $U'(S)$ .

## 4.2 Considering copiers

We next consider existence of copiers. We first need to decide the probability that an update  $U$  is independent. At each observation point  $t$ , for each pair of sources  $S_1$  and  $S_2$ , we can compute the probability that  $S_1$  is actively copying from  $S_2$ , denoted by  $P(S_1 \rightarrow S_2, t)$ . We consider  $S_1$  being a copier of  $S_2$  at  $t$  if the probability of state  $I$  at  $t$  is less than .5 and the probability of  $S_1$  being a copier ( $P(C1_c) + P(C1_{-c})$ ) is larger than that for  $S_2$ . Given an update  $U$  at time  $t$ , we consider the probability of  $U$  being copied from  $S_2$ , denoted by  $P(S_1 \xrightarrow{U} S_2)$ , as  $P(S_1 \rightarrow S_2, t)$  if (1)  $S_1$  is a copier of  $S_2$  at  $t$ , (2)  $S_2$  provides the same value for  $O$  at  $t$ , and (3)  $S_2$  makes that update no later than  $U$ , and as 0 otherwise. We assume copying between sources are independent; thus, the probability of  $S_1$  independently making an update  $U$  is

$$P(U \text{ indep}) = \prod_{S_2 \in \mathcal{S}, S_2 \neq S_1} (1 - P(S_1 \xrightarrow{U} S_2)). \quad (28)$$

When we compute  $P(\Phi | T(O))$ , we revise Equation (25):

$$P(\Phi | T(O)) = \prod_{S \in \mathcal{S}} P(U(S) | T(O))^{P(U(S) \text{ indep})}. \quad (29)$$

Finally, we note that our copying discovery techniques cannot avoid a transitive inference of loop copying among more than two sources, and we can end up marking the same updates at the same time by sources in the loop all as copied (with a probability). However, such coincidence is typically rare and can be ignored.

## 4.3 Putting them all together

Finally, we consider how we decide the life span of each object given updates by each source. In this process, we should consider copying between sources and CEF-measure of sources. However, discovering source copying requires knowledge of the life span of each object and the CEF-measure of each source, and computing CEF-measure requires knowledge of life spans of objects.

Our algorithm thus proceeds in an iterative fashion. In each round, we first compute the CEF-measure of each source (depending only on life spans), then compute the probability of copying between sources, and finally (re)decide the life span of each object, until the discovered life spans do not change. Note that in the first round we do not know the life span yet; we initialize the CEF-measure of each source to the same default value except setting the coverage as the percentage of objects being covered by the source; and we assume each update has a probability of .5 to be true when applying the HMM model for copying detection.

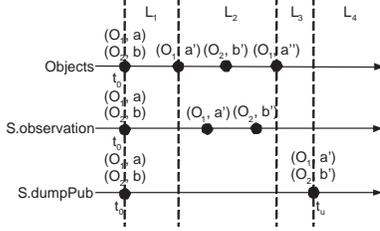

Figure 9: Different types of delayed publishing.

Fig. 8 shows the complete algorithm. Convergence of the algorithm remains an open problem, but in our experiments we observe that when the total number of transitions is far more than the number of sources, the algorithm converges quickly. Time complexity of each round is shown as follows.

**PROPOSITION 4.2.** *Let  $m$  be the number of values in the domain of an object, and  $u$  be the total number of updates by sources in  $\mathcal{S}$ . We denote by  $|\bar{X}|$  the size of set  $\bar{X}$ . Then, complexity of one round in Algorithm LIFESPAN is  $O(|\mathcal{O}| \cdot |\mathcal{S}|^2 \cdot |\mathbf{T}| + m \cdot |\mathcal{O}| \cdot |\mathcal{S}| \cdot |\mathbf{T}|^2 + u \cdot |\mathcal{S}|)$ .  $\square$*

**EXAMPLE 4.3.** *Consider Example 2.1. Table 5 shows the life span discovered for Halevy. The algorithm converges in four rounds. The CEF of  $S_1$  converges at a high coverage and exactness, whereas that of  $S_2$  converges at a low coverage and exactness.  $\square$*

## 5. CONSIDERING DELAYED PUBLISHING

Previous sections assume instant publishing. In this section we consider *delayed publishing*, where a source can publish an update later than the change is observed (from the real world or from other sources). Delayed publishing can happen when a weekly newspaper publishes news collected through the whole week, when a web portal publishes data crawled in a period of time in a batch mode, when we observe only a subset of sources each time, and so on. We assume *dump publishing*, where a source publishes all data it has collected since the last publishing. This is common in practice and our techniques can be easily extended to the case where a source publishes only a subset of collected data each time, but does so in an ordered manner.

In dump publishing, an update decision can be made at any point between two consecutive publishings; we revise our models accordingly to consider all possibilities.

**CEF-measure** To compute CEF-measure, we need to decide if a slice is captured or mis-captured. In case of delayed publishing, if a slice  $L$  ends with an update  $U$ , but the previous publishing happens before the beginning of  $L$ , then  $U$  may actually tend to capture the value of  $L$ 's previous slices. As an example, in Fig. 9, the update  $(O_1, a')$  at  $t_u$  is to capture the value of slice  $L_2$ , not  $L_3$ .

Formally, consider source  $S$  and object  $O$ . Let  $L_1, \dots, L_k, k \geq 1$ , be a set of consecutive slices for  $S$  and  $O$ , such that  $L_k$  ends with an update  $U$  on  $O$ , and the previous publishing  $Pub$  happens in slice  $L_1$ . Let  $l_1$  be the difference between the time of publishing  $Pub$  and the end of slice  $L_1$ , and let  $l_i, i \in [2, k]$ , be the length of  $L_i$ . Then, with probability  $p_i = \frac{l_i}{\sum_{j=1}^k l_j}, i \in [1, k]$ ,  $U$  is collected (though not published) in slice  $L_i$ . Accordingly,  $L_i$  is captured by  $U$  with probability  $p_i$  if  $U$  provides the real value of  $L_i$ , and mis-captured with probability  $p_i$  otherwise. We thus compute  $c(S, O)$  and  $m(S, O)$  by summing up the corresponding probabilities. Similarly, when we compute freshness, if a slice  $L_i, i \in [1, k]$ , is captured, we consider equal likelihood of the update being captured at any time in  $L_i$ .

**Life span** Deciding the next transition  $T(O)$  relies on computing the conditional probability of  $U(S) = (t_u, v_u)$ . Assume  $S$  previously publishes at time  $t_{pre}, pre \in [0, u]$ . Then the update is published at  $t_u$  once the source decides to make the update at some time in  $(t_{pre}, t_u]$ , so we should take the sum of the probabilities:

$$P(U(S, T) = (t_u, v_u) | T(O)) = \sum_{i=pre+1}^u P(U(S) = (t_i, v_u) | T(O)). \quad (30)$$

**Copying** When deciding source copying, we need to compute the probability of a source independently making an update at a particular time,  $P(U, S_1, t_u | S_1 \not\rightarrow S_2)$ . In case of delayed publishing, an update decision actually can be made at any time after the previous publishing  $t_{pre}$ ; the probability of the decision at a particular observation point is proportional to the length of that observation period. We thus take the weighted average of the probabilities (note the difference from computing  $P(U(S) = (t_u, v_u) | T(O))$ ):

$$P(U, S_1, t_u | S_1 \not\rightarrow S_2) = \sum_{i=pre+1}^u P(U, S_1, t_i | S_1 \not\rightarrow S_2) \cdot \frac{t_i - t_{i-1}}{t_u - t_{pre}}. \quad (31)$$

In addition, when we decide the independence probability of an update  $U$  by  $S_1$ , we consider that  $U$  is possibly copied from  $S_2$  if the updated value is the same as a value once provided by  $S_2$  since the last publishing of  $S_1$ .

## 6. EXPERIMENTAL RESULTS

This section presents experimental results on life-span discovery and copying detection. We first present results on a real-world data set (Sec. 6.2), showing that the problems we address in this paper are real issues in the world, and our methods can improve quality of the integrated data. Since in most cases we have no means to check the actual copying relationship and the precise life span of objects in the real world, we also experimented on synthetic data. We first present results on a data set that mimics complexity in the real world, examining contribution of different components to our algorithms (Sec. 6.3.2). We then consider a harder case, where we care about only existence of sources so variety of update traces by different sources significantly reduces. We examine the performance and robustness of our models on life-span discovery (Sec. 6.3.3) and copying detection (Sec. 6.3.4).

### 6.1 Experiment setup

We consider a set of data sources and objects as described in Sec. 2 and refer to them as a *universe*. We refer to the special case where each object has only two possible values, existing and non-existing ( $\perp$ ), as *binary universe*. Our goals are to decide life span of objects and copying between sources in a given universe.

For life-span discovery, our algorithm has three main components: *copy*—considering copying between sources, *CEF*—considering CEF-measure of sources, and *delay*—considering publish delay. We implemented several variants by combining different components.

- **NAIVE**: For each object, vote for its value at each observation point.
- **SIMPLE**: First apply NAIVE and then decide transition points iteratively: for each point  $t$  where the voted value changes to a new value  $v$ , find the earliest point since the last transition when a source provides  $v$  and does not update until point  $t$ .
- **COPY**: The same as SIMPLE except considering copying in voting (Eq. (28)).
- **CEF**: Consider CEF-measure (Eq. (20-27)).
- **CEFDelay**:  $CEF + delay$  (Eq. (30)).

**Table 5: Discovered life span for *Halevy* and computed CEF-measure for  $S_1$  and  $S_2$  in Example 2.1.**

Round	Life span for <i>Halevy</i>	$S_{1,C}$	$S_{1,E}$	$S_{1,F(0)}$	$S_{1,F(1)}$	$S_{2,C}$	$S_{2,E}$	$S_{2,F(0)}$	$S_{2,F(1)}$
0		.99	.95	.1	.2	.99	.95	.1	.2
1	(2000, Wisc), (2002, UW), (2003, Google)	.97	.94	.27	.4	.57	.83	.17	.3
2	(2000, UW), (2002, Google)	.92	.99	.27	.4	.64	.8	.18	.27
3	(2000, UW), (2005, Google)	.92	.99	.27	.4	.64	.8	.25	.42

**Table 6: Discovered ever-existing restaurants (#Rest) and closed restaurants in Manhattan. We skip results of COPYCEFDelay as almost all sources update every week, and skip results of SIMPLE and COPY, which are similar to NAIVE.**

Method	Ever-existing	Closed			#Rnds	Time(s)
	#Rest	Prec	Rec	F-msr		
ALL	-	.60	.1	.75	-	-
ALL2	-	.94	.34	.50	-	-
NAIVE	1192	.70	.93	.80	1	158
CEF	5068	.83	.88	.85	7	637
COPYCEF	5186	.86	.87	.86	6	1408
GOOGLE	-	.84	.19	.30	-	-

- COPYCEF: *copy*+CEF. (Algorithm LIFESPAN).
- COPYCEFDelay: *copy*+CEF+delay (Eq. (30-31)).

For copying discovery, we compared static models (INIT, CURR, TRACE), various HMM models (HMM5, HMMN, HMM3), and HMM with consideration of publish delay (HMMDELAY):

- INIT/CURR: Consider only initial or latest values.
- TRACE: Compute  $\Omega_1$  and  $\Omega_2$  for each observation point and reason over the accumulated results (Eq. (16-18)).
- HMM3: An HMM model with three states  $I$ ,  $C_{1c}$ , and  $C_{2c}$ , the same transition probabilities as Fig. 3 except that  $a_{I,I} = t_i - f$ ,  $a_{I,C_{1c}} = a_{I,C_{2c}} = \frac{1-t_i+f}{2}$ ,  $a_{C_{1c},I} = a_{C_{2c},I} = (1-t_c)t_i + t_c(1-f)$ .
- HMM5: The basic HMM model with 5 states (Fig. 3).
- HMMN: The timespan HMM model (Fig. 5) with  $f(i) = \frac{i+f}{i+1}$ ,  $q = 5$ .
- HMMDELAY: HMM5 with publish delay (Eq. (31)).

By default, we computed weighted CEF-measure and applied HMM5 in life-span discovery. Initially we set  $\alpha = f = .5$ ,  $t_i = t_c = 0.99$ ,  $s = .8$ ,  $m = 100$ , but may apply *Baum-Welch* learning to learn the parameters in some experiments.

We measure life-span discovery results by *edit distance*, defined as the Levenshtein distance between decided life-span periods and real periods, where insertion or deletion of a period is penalized by the length of the period, and substitution of a period with the same value is penalized by the difference of the beginning points. Ideally, the edit distance should be 0. We describe how we measure copying-detection results in Sec. 6.3.4.

We implemented our models in Java and conducted experiments on a WindowsXP machine with AMD Athlon(tm) 64 2GHz CPU and 960MB memory.

## 6.2 Experiments on real-world data

We randomly selected 12 web sources (listed in Table 1 at the beginning of this paper; the source freshness uses  $F(S, 0)$  for each source  $S$ ) that provide information on restaurants in Manhattan. We crawled their data from 1/22/2009 to 3/12/2009, once every week, so 8 times in total. For each restaurant listing, we collected name, phone number, address, direction, neighborhood, and price range whenever possible. We identified restaurants by their names and considered only restaurants that are mentioned by at least two data sources. In total there are 5269 such restaurants; among them,

5231 appeared in our first crawling, and 5251 appeared in our last crawling. In these two months, we did not notice many changes on attribute values such as phone and address, thus focused on existence of restaurants (so a binary universe).

We considered two cases as deletion of a restaurant from a source: the source explicitly marks the restaurant as “(CLOSED)”, or the source implicitly removes the restaurant from its list. We considered the set of restaurants that a source provided once but deleted later. There are 467 such restaurants. For each of them, we called its phone number to verify if it is still open and used it as the golden standard; we found that 280 of them are indeed closed<sup>5</sup>. We ran various algorithms to decide life span (existence periods) of each restaurant, and reported *precision*, *recall*, and *F-measure*, denoted respectively as  $P$ ,  $R$ ,  $F$ , of our results. Formally, among the 467 restaurants, we define  $\bar{G}$  as the set of restaurants that are closed in the golden standard and  $\bar{R}$  as the set of restaurants that our algorithm decided as closed. Then,  $P = \frac{|\bar{G} \cap \bar{R}|}{|\bar{R}|}$ ,  $R = \frac{|\bar{G} \cap \bar{R}|}{|\bar{G}|}$ , and  $F = \frac{2PR}{P+R}$ . In addition, we searched each of the restaurants on Google Maps and reported the three measures as well.

Table 6 shows results of various methods. We observed as follows. (1) COPYCEF and CEF obtain high precision and recall. Between them, COPYCEF considers copying and thus obtains higher precision and discovers more restaurants that have ever existed. (2) NAIVE seems to have a high F-measure; however, as most restaurants are often mentioned by only a few sources, it concludes that only 1192 out of 5269 restaurants have ever existed. (3) Considering all of the 467 restaurants as closed (referred to as ALL) has low precision (.60), while considering only restaurants that are removed by at least two sources as closed (referred to as ALL2) has low recall (.34). Finally, we observed that Google Maps lists many out-of-business restaurants, reflecting staleness of data on the web.

Among the 66 pairs of sources, we detected copying relationship between 12 pairs (Fig. 1). Among the sources, it is more likely that *FoodBuzz*, *VillageVoice*, and *OpenTable* are copiers and *MenuPages* and *TimeOut* are being copied. Although we do not know the real copying relationship, we have the following evidence to support some of our results. First, *FoodBuzz* and *VillageVoice* each formats addresses of different restaurants in very different ways, so may copy them from various sources; in addition, *FoodBuzz* inserted restaurants even after the restaurants were closed, so possibly copied the data. Second, *MenuPages* has been on the web for the longest time among the 12 sources and has the highest coverage (.66), so it is possible that it was copied by other sources.

We observed that COPYCEF and CEF both converged at the 5th round and took 23.5 and 10.6 minutes respectively. Since life-span discovery is a one-time process, the execution time is acceptable.

## 6.3 Experiments on synthetic data

We next describe how we generated the synthetic data and reported experimental results.

### 6.3.1 Synthetic data

**Objects:** A universe contains 100 objects. In a multi-valued universe, the domain for each object contains 102 values (including

<sup>5</sup>Some of the 280 restaurants were closed before 1/22/2009 and were already marked “(CLOSED)” by some sources on 1/22/2009.

**Table 7: Source-generation parameters and their settings.**

Parameter	$p_t$	$p_f$	$f_0$	$f_u$	$ns_u$	$os_u$	$a_u$
Default	.75	.99	.1	.5	.8	.2	.075
Range	0-1	.95-1	.1-1	.1-1	.1-1	.2	0-.15

⊥). We have 20 periodical observations at  $t_0, \dots, t_{19}$ . A universe can be either *single-period* or *multi-period*: in the former an object exists at  $t_0$  with probability  $p_i = .5$  and at  $t_{19}$  with probability  $p_e = .3$ , and a transition happens with a random value at a random observation point; in the latter an object exists at  $t_0$  with probability  $p_i = .5$ , transits at each point with probability  $p_c = .1$ , and once transits, disappears with probability  $p_e = .1$  or changes to another random value. We note that results with more objects, more observations, or larger domains show similar patterns.

**Sources:** According to different types of data sources, we classify a universe into three categories.

- *Independence universe* contains 10 independent sources.
- *Copier universe* contains 10 independent sources and 9 copiers, all copying from the same independent source.
- *Random universe* contains 10 independent sources and a number of copiers. Each copier copies from a randomly selected source, either independent or being a copier as well, but there is no loop copying.

For each independent source  $S$  and object  $O$ , at each observation point  $S$  updates the value of  $O$  to a random false value with probability  $p_f$ , and updates to the true value with probability  $p_t \cdot f(\Delta)$ , where  $\Delta$  is the difference between the observation and the transition of that true value. We define  $f(\Delta) = f_0 \cdot 2^\Delta$  when  $0 \leq \Delta \leq -\log f_0$ , and  $f(\Delta) = 1$  when  $\Delta > -\log f_0, 0 < f_0 \leq 1$ . Note that although  $p_t, p_f$  and  $f$  are related to the CEF-measure, the definitions are not exactly the same and we chose to do so to test robustness of our model. Table 7 shows how we set the parameters. For the *random universe*, we randomize  $p_t, p_f, f_0$  by Gaussian distribution with mean .75, .95, .1 respectively.

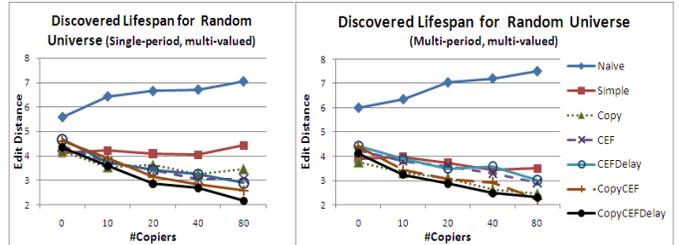

For each copier  $C$  and its original source  $S$ , at each observation point,  $C$  copies from  $S$  with probability  $f_u$ . For the *copier universe*, when  $C$  copies, with probability  $ns_u$  it copies a value provided by  $S$  since last copying and with probability  $os_u$  it copies a value provided by  $S$  earlier. For each object on which it does not copy, with probability  $a_u$  it independently provides the true value; Table 7 shows setting of these parameters. For the *random universe*, we randomize  $f_u, ns_u, a_u$  by Gaussian distribution with mean .5, .8, .1 respectively; when a copier does not copy on a particular object, it examines the object with probability  $a_u$  and provides a value according to  $p_t, p_f$  and  $f$ .

By default we consider instant publishing and no transformation between being a copier and being independent; though, we consider different settings in some experiments. In the *random universe*, half initial independent sources and half initial copiers can transform between being independent and being a copier, and the probability of transformation at each observation point is .1. Once a source transforms to a copier, it can choose a source it has not copied from before. Among each kind of sources, half sources publish instantly and half can delay publishing.

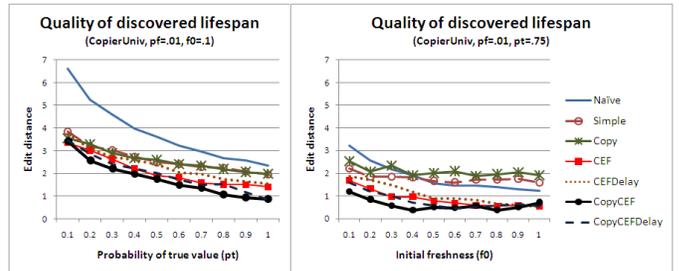

For each setting, we ran the experiments 10 times and reported the average measure.

### 6.3.2 Results for multi-valued universe

Fig. 10 shows results of various methods for the *random universe*, which tries to mimic the complexity of the real world. We considered both single-period life span and multi-period life span

**Figure 10: Life-span discovery for the random universe. COPYCEFDelay always obtains the best results.**

**Figure 11: Life-span discovery for copier universe with instant publishing. COPYCEFDelay always obtains the best results while COPYCEFDelay obtains slightly worse results. We observed similar trends when  $p_f$  is higher, but higher edit distance for each method.**

and have several observations. (1) COPYCEFDelay obtains the best results in most cases: when there are 80 copiers, it reduces the edit distance by 51% compared with SIMPLE and by 69% compared with NAIVE in the multi-period case. (2) COPYCEF obtains slightly worse results, but performs better than other methods. (3) CEF and COPY have similar results and improve over SIMPLE. Note that in case of multi-period life spans, the improvement by CEF is slight, as the length of each period tends to be short and the CEF-measure may not be computed accurately.

We next test robustness of our model on various settings of parameters for universe generation. We describe our results on the binary universe, which forms a harder case, but observed similar trend on multi-valued universe as well.

### 6.3.3 Life-span discovery for binary universe

**Quality of sources:** First, we compared various methods on the *copier universe* when we varied quality of the independent sources (Fig. 11). We make the following observations. (1) CEF obtains better results than NAIVE and SIMPLE in all different settings. (2) COPY obtains similar, but sometimes even worse results than SIMPLE, showing that considering copying in itself is not enough in binary universe. Once we consider both copying and CEF-measure, the results are significantly improved: when  $p_f = .01$  and  $f_0 = .1$ , on average COPYCEF reduces the edit distance by 27.8% over SIMPLE and by 18.3% over CEF. (3) CEFDELAY and COPYCEFDelay obtain slightly worse results than CEF and COPYCEF respectively, showing that considering publish delay in case of instant publishing does lose information, but only slightly. (4) Typically, COPYCEF obtains better results with higher CEF-measure (lower  $p_f$ , higher  $p_t$  or  $f_0$ ). The only exception is when the CEF-measures are all very high, so all sources are highly similar and COPYCEF can wrongly identify an independent source as a copier.

We observed similar trends on the *independence universe*, except that COPYCEF and CEF obtain similar results, showing no negative effect in considering copying when there is no copiers.

**Quality of original source:** We varied quality of the source that is

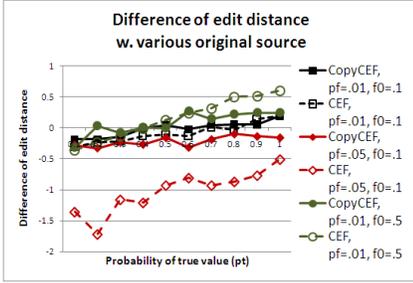

Figure 12: COPYCEF is robust to the quality of the source being copied.

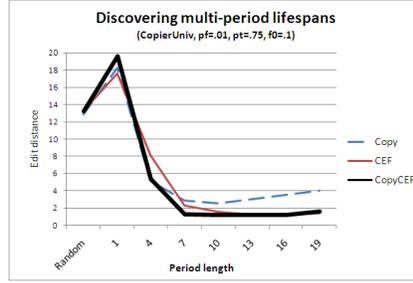

Figure 13: COPYCEF obtains better results with longer-period life spans.

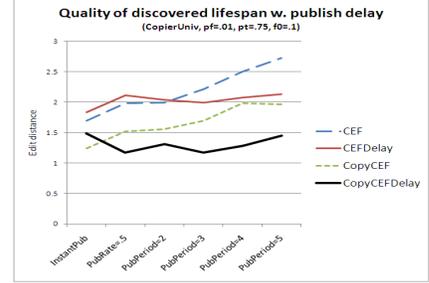

Figure 14: COPYCEFDelay is robust to publish delay.

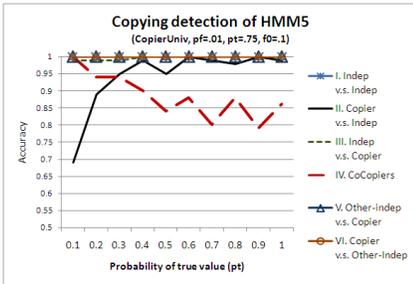

Figure 15: Copying detection of HMM5.

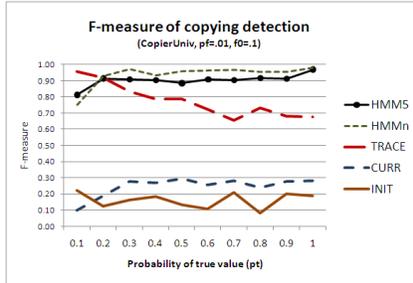

Figure 16: HMMN obtains the highest F-measure.

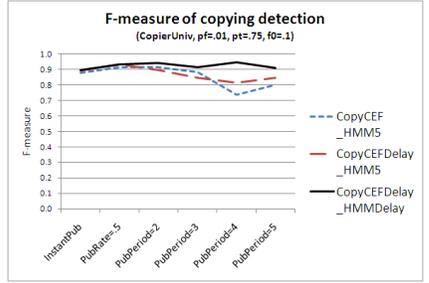

Figure 17: HMM5Delay is not sensitive to publish delay.

copied while applied the default parameters for other independent sources. Fig. 12 shows difference of the edit distance when all independent sources have the same quality and that when the source being copied has different quality. We observe that the difference for COPYCEF is very low, and much lower than that of CEF; for example, when  $p_f$  increases from .01 to .05 and  $p_t$  decreases from .75 to .1, the edit distance of the results increases only by .28, while the difference for CEF is 1.36. Thus, COPYCEF is insensitive to quality of the sources that are copied.

**Multi-period life spans:** We constructed multi-period life spans in two ways: (1) randomly generate multiple periods observing  $p_i = .5, p_c = .3$ ; (2) randomly choose the first existence point in  $[0, l - 1]$ , and generate life span with periods of length  $l$ . Fig. 13 shows the results of COPY, CEF and COPYCEF. We observe that COPYCEF obtains the best results in most cases. For all models, the edit distance significantly decreases when the average length of the periods increases; the edit distance remains stable once the length reaches 10, as beyond this point the average length of existing and non-existing periods remains as 10. Thus, COPYCEF performs better when life-span periods are longer.

**Publish delay:** We constructed sources with delayed publishing in two ways: (1) each source publishes at the beginning and then publishes at a particular observation point with probability .5, (2) each source publishes at the beginning, randomly chooses the second publish point in  $[1, d]$ , and then publishes after every  $d$  observations. Fig. 14 shows the results. COPYCEFDelay obtains the best results when there exists publish delay: edit distance of its results remains stable as  $d$  increases; on average it improves over COPYCEF by 26% in presence of delayed publishing; and in general, the higher the publish delay, the larger improvement. Thus, COPYCEFDelay handles publish delay well.

### 6.3.4 Copying detection for binary universe

We next compare different models for copying detection.

**Overtime copier** We start with the case when a copier does not

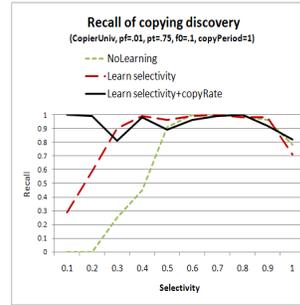

Figure 18: HMM5 w. learning is robust to initial parameter settings.

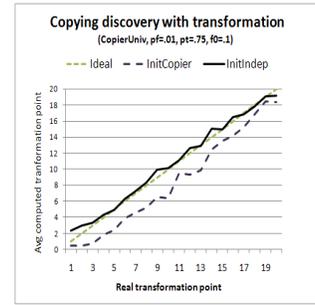

Figure 19: HMM5 is good at detecting transformations of copiers.

transform to be independent. We examine accuracy of copying decision for the following categories: I. two independent sources, II. a copier vs. its original source, III. a source vs. its copier, IV. two co-copiers, V. an independent source vs. a copier of another source, and VI. a copier of a source vs. another independent source.

In addition, we measure discovered copying by precision, recall and F-measure. Let  $\bar{G}$  be the set of ordered pairs  $(S_1, S_2)$  where  $S_2$  is a copier of  $S_1$ , and  $\bar{R}$  be such pairs returned by our model. We compute the three measures as we described earlier. To prevent a particular category from dominating the results, we divided the universe into sub-universes, each containing two copiers, their original source, and another independent source (so two pairs in each of the six categories), and take the average over sub-universes. Note that the recall equals the accuracy of Category II.

We start with analysis of HMM5. Fig. 15 shows its accuracy on various categories of source pairs. We observe that (1) HMM5 is good at identifying copiers: in Category II, when the coverage is above .2, we obtain an accuracy of above 95%; we can miss copiers when the coverage is low because the copiers actually conduct more independent updates than copied updates, so are hard to

be distinguished from independent sources; (2) HMM5 achieves an accuracy of nearly 1 for identifying sources that are independent of each other (I, V, VI); (3) The only category for which HMM does not do very well is between co-copiers (IV), as they share similar update patterns; however, the accuracy is still 88% on average.

We then compared various methods for copying detection in terms of their F-measures (Fig. 16) and their effect on results of COPY-CEF (figure omitted for space consideration). First, considering only a snapshot of data obtains very low precision and recall (on average  $F1=.25$  for CURR and  $F1=.16$  for INIT). Second, TRACE obtains a low precision and significantly worsen results of COPY-CEF, especially when  $p_t$  is high; this is because it accumulates a lot of overlapped updates over time and so is likely to conclude copying. Third, although we cannot compare HMM3 and HMM5 directly on F-measure of copying detection, we observe that the edit distance of discovered life span using HMM3 is 6.7% larger than HMM5, as HMM3 does not distinguish an independent source and an idle copier (not copying). Finally, HMMN obtains the highest F-measure in most cases by asserting that the longer a copier has not copied, the more likely it should copy next; however, it does not improve results of COPYCEF much.

Next, we compared HMM5 and HMMDELAY when there is publish delay (Fig. 17). HMMDELAY indeed improves over HMM5 by 8.5% on recall, 4.3% on precision, and 6.5% on F-measure on average, but has no obvious effect on life-span discovery.

Finally, we examined whether our model is robust with respect to different copy patterns by varying the selectivity of copying ( $s_u$ ) from .1 to 1, and changing the copy rate to 1. We observe similar precision and show only recall. Fig. 18 shows that if we use the default selectivity (.8) in our HMM model, we can obtain a low recall when  $s_u$  is low (below .5). If we learn selectivity, the recall increases from .63 to .84 on average; if we learn copy rate in addition, the recall increases further to .94 and is high for almost all different values of  $s_u$ . The results show robustness of our HMM model to different initial settings of parameters.

**Copying transformation** We considered transformation and generated copiers that are initially copiers or independent sources, and then transform at a particular point. We compared the transformation points our model computes with the real ones; if the copier does not transform, we consider that the transformation point is 20 (the number of observations). Fig. 19 shows the average transformation points that HMM5 computes. On average the difference between real transformation points and those computed by HMM5 is small: 2 when the copiers are initially copying, and .44 when they are initially independent.

**Summary** Our experimental results on synthetic data have the following implications:

1. Considering CEF-measure and copying both contribute to improving quality of life-span discovery results.
2. Considering publish delay can significantly improve the results in presence of delay, and only slightly worsen the results in absence of delay.
3. The basic HMM model is accurate in detecting copying; the timespan HMM model improves the results only slightly, but with higher cost.
4. Our model is robust to different characteristics of data and initial HMM parameter settings.

## 7. RELATED WORK

There are three bodies of work related to our research: *truth discovery*, *copying detection* and *data freshness*. Recent work on truth

discovery considers a snapshot of data (surveyed in [6]). We consider discovering the whole life span of an object from history of source updates and we use more fine-grained source-quality measures: coverage, exactness, and freshness.

For copying detection, Berti-Equille et al. [1] recently sketched several high-level intuitions, but did not give concrete algorithms. Dong et al. [5] proposed detecting copying from a snapshot of data by examining overlapping errors between sources; such a model, however, can fall short in presence of large overlap of out-of-date data. We consider update history of sources in copying detection and decide in which period a source is a copier and at which particular moments it copies. We are not aware of any other work for copying detection on relational data. In addition, we distinguish our work from *data provenance* [2], which assumes knowledge of provenance and focuses on management of such information.

Finally, existing work on data freshness [3, 7, 8, 9, 11] defines *freshness* as how stale the data in a materialized view are compared with the original sources, and emphasize update propagation. We have a different focus and consider consistency of data with respect to evolution of real-world objects over time. We note that the notions of *completeness*, *consistency*, and *currency* in [7] are analogous to our CEF-measure, but in a different context.

## 8. CONCLUSIONS

This paper considers how we can explore update history of sources in improving quality of integrated data. We measure quality of source data by coverage, exactness, and freshness, and accordingly developed an HMM model to decide copying relationship between sources. Then, we developed a Bayesian model to decide life span of each object. Experimental results on real-world and synthetic data show high accuracy and efficiency of our models.

For future work, one direction is to apply our techniques in Web 2.0 applications to identify sources or users that are trustable. Another direction is to optimize query answering in data integration with knowledge of source quality and dependence.
